Causal Exaggeration

Vincent Bagilet *

Abstract

The credibility revolution in economics has made causal inference methods ubiquitous. At the same time, an increasing amount of evidence has highlighted that the literature strongly favors statistically significant results. I show that these two phenomena interact in a way that significantly worsens the reliability of published estimates: while causal inference methods can successfully reduce bias caused by confounders, the accompanying reduction in statistical power can create another type of bias, leading published estimates to exaggerate true effects sizes. I document this trade-off using realistic fake data simulations and a formal mathematical derivation. I then discuss potential avenues to address it.

*Columbia University, New York, USA. Email: vincent.bagilet@columbia.edu. A previous version of this project, entitled "*Unconfounded but inflated causal estimates*", was co-authored with Léo Zabrocki-Hallak, I cannot thank him enough for his invaluable and far-reaching contributions to the project. I am very grateful to Hélène Ollivier and Jeffrey Shrader for their guidance and thank Sylvain Chabé-Ferret, Jesse McDevitt-Irwin, David McKenzie, José Luis Montiel Olea, Suresh Naidu, Claire Palandri, Julian Reif, Stephan Thies and Roberto Zuniga Valladares for helpful comments, as well as lab members at Columbia and seminars participants at Columbia, IPWSD, the Paris School of Economics and the Toulouse School of Economics.

I Introduction

One of the main challenges of empirical economics is to reduce confounding to identify causal effects. Identifications strategies such as Regression Discontinuity (RD), Instrumental Variable (IV), Difference-in-Differences (DID) and event studies help us achieve this goal. To do so, these strategies only use part of the variation in the data. They exploit the exogenous part of the variation in the treatment or decrease the sample size by only considering observations for which the as-if random assignment assumption is credible. Reducing the variation used can decrease precision and thus statistical power, that is to say the probability of rejecting the null hypothesis of no effect when it is false. In this paper, I argue that this often creates a tension between statistical power and reducing confounding.

When statistical power is low, not only the estimator is imprecise as we well know but statistically significant estimates exaggerate the true effect size (Ioannidis 2008, Gelman and Carlin 2014, Lu et al. 2019, Zwet and Cator 2021). Only estimates at least two standard errors away from zero are statistically significant at the 5% level. In under-powered studies, these estimates make up a selected sub-sample of all estimates, located in the tails of the distribution of all possible estimates. The average of these statistically significant estimates differs from the true effect, located at the center of the distribution if the estimator is unbiased. When power is low, obtaining a statistically significant estimate from an unbiased estimator does not guarantee that it will be close to the true effect. An estimate $\hat{\beta}$ of β might be unbiased in the traditional sense of $\mathbb{E}[\hat{\beta}] = \beta$ but conditionally biased in the sense that $\mathbb{E}[\hat{\beta}|\text{ Significant}] \neq \beta$. Figure 1 illustrates the inflation of significant estimates caused by imprecision.

This consequence of low statistical power could be non-problematic if a large literature had not underlined the existence of a publication bias favoring statistically significant results (Rosenthal 1979, Andrews and Kasy 2019, Abadie 2020, Brodeur et al. 2020, for instance). Published estimates from under-powered studies thus form a biased sample of the distribution of all estimates and can greatly exaggerate true effect sizes. This participates to the current replication crisis affecting various fields such as economics, epidemiology, medicine or psychology (Button et al. 2013, Open Science Collaboration 2015, Camerer et al. 2016, Chang and Li 2022). Even in experimental economics, with a high level of control and an arguable absence of confounders, estimates published in top economic journals that have been replicated were on average inflated by a factor of at least 1.5 (Camerer et al. 2016). Quasi-experimental studies are likely even more exposed to this exaggeration issue as, in current practices, statistical power is not central to observational analyses. Ioannidis et al. (2017) concernedly finds that the median statistical power in a wide range of economic studies is no more than 18% and that nearly 80% of estimates may be exaggerated by a factor of two, despite the widespread use of convincing causal identification strategies and usually large sample

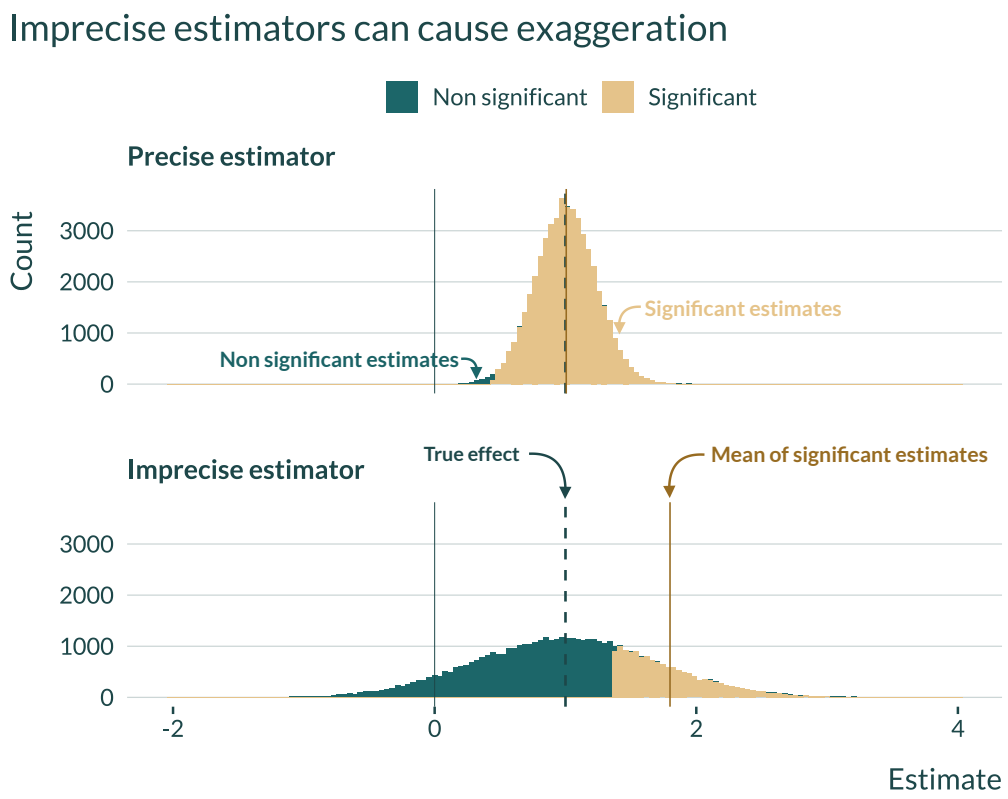

Figure 1 – Significance and distribution of two unbiased estimators with different variances

sizes. The magnitude of exaggerations is thus considerable and in some situations could be on par with that of bias caused by confounders. It is thus crucial to take exaggeration risks into account.

In this paper, I propose an overarching mechanism that may contribute to explaining these inaccuracies in published estimates. I show that design choices in quasi-experimental studies can be seen as a trade-off between avoiding confounding and overestimating true effect sizes due to a resulting loss in power. To limit the threat of confounding, causal inference methods discard variation and therefore reduce statistical power. This can result in inflated significant and published estimates. While causal identifications strategies are essential to describe causal relationships, this paper emphasizes that a perfectly convincing identification does not guaranty an absence of "bias" and that improving identification can actually pull us away from the true effect. In some settings, reaching unbiasedness can actually be impossible as getting rid of bias caused by confounders creates another type of bias.

While the general idea that causal inference methods discard variation to identify effects is shared across strategies, the confounding / exaggeration trade-off is mediated through a distinctive channel for each of them. In RD designs, even when the initial sample size is large, we discard part

of the variation by only considering observations within the bandwidth, decreasing the effective sample size and thus precision. In an IV setting, we only use the subset of the variation in the treatment that is explained by the instrument. In event studies, the variation used to identify an effect sometimes only comes from a limited number of changes in treatment status. When all confounders are measured, matching has a causal interpretation but it still prunes treated units that cannot be matched to untreated ones. Generic controls or fixed effects can increase the variance of the estimate and exaggeration if they absorb more of the variation in the treatment than in the outcome variable.

Since causal identification strategies can be interpreted as ways of controlling for confounders, this last point actually ties all the strategy specific arguments together. We implement Fixed Effects (FEs) based identification strategies such as DiD to control for the invariant, unobserved and arguably endogenous part of the variation in the outcome. In the Control Function (CF) approach of IV, we control for the predicted residuals of the regression of the endogenous variable of interest on the instrument. Fuzzy-RD and propensity score matching can also be thought of as control function approaches, of the forcing variable and propensity score respectively. In addition, excluding observations that are outside the bandwidth or unmatched is equivalent to controlling for observation level fixed effects for these observations. When these methods for controlling for confounders absorb more of the variation in the treatment than in the outcome, they will increase the variance and cause exaggeration. Considering a simple linear homoskedastic model gives the intuition for this trade-off between exaggeration and omitted variable bias for control approaches. Let $y_i = \alpha + \beta x_i + \delta w_i + u_i$, $\forall i \in \{1, .., n\}$, with w potentially unobserved. Under usual assumptions and using the Frisch-Waugh-Lovell theorem we get that σ^2_{OVB} and σ^2_{CTRL}, the variance of the estimators for β when omitting w (short regression) and controlling for it (long regression) respectively are:

$$\sigma^2_{\text{OVB}} = \frac{\sigma^2_{u_{\text{OVB}}}}{n\ \sigma^2_x} = \frac{\sigma^2_{y^{\perp x}}}{n\ \sigma^2_x} \qquad \text{and} \qquad \sigma^2_{\text{CTRL}} = \frac{\sigma^2_{u_{\text{CTRL}}}}{n\ \sigma^2_{x^{\perp w}}} = \frac{\sigma^2_{y^{\perp x,w}}}{n\ \sigma^2_{x^{\perp w}}}$$

and thus,

$$\sigma^2_{\text{OVB}} < \sigma^2_{\text{CTRL}} \quad \Leftrightarrow \quad \frac{\sigma^2_{y^{\perp x}}}{n\ \sigma^2_x} < \frac{\sigma^2_{y^{\perp x,w}}}{n\ \sigma^2_{x^{\perp w}}} \quad \Leftrightarrow \quad \frac{\sigma^2_{x^{\perp w}}}{\sigma^2_x} < \frac{\sigma^2_{y^{\perp x,w}}}{\sigma^2_{y^{\perp x}}}$$

Controlling will increase the variance of the estimator if the fraction of the variance unexplained by w is greater for $y^{\perp x}$ than for x. Put differently, if controlling absorbs more of the variation in x than in the residual part of y ($y^{\perp x}$), it will increase the variance of the estimator. As briefly discussed above, since exaggeration increases with the variance of the estimator, controlling may increase exaggeration. I develop this intuition and a formal proof showing that exaggeration can

be larger when controlling, even when accounting for bias, in section III.

In the remainder of the paper, I first illustrate the existence of this "causal exaggeration" using examples drawn from education, labor, environmental and political economics. The exaggeration of statistically significant estimates can be defined as the ratio of the estimated effect over the true effect, which is never known in a real world setting. To know the true effect and be able to compute this quantity, I have to turn to simulations. Since my fake-data Monte-Carlo simulations have an illustrative purpose only, I intentionally focus on settings in which statistical power can be low. All other simulation assumptions are chosen to make it easier to retrieve the effect of interest. I consider simple linear models with constant treatment effects, i.i.d. observations and homoskedastic errors. All the models are correctly specified and accurately represent the data generating process, except for the omitted variable.

Then, I develop the mathematical intuition behind the confounding / exaggeration trade-off through the tying interpretation of causal identification strategies as control strategies. I also derive a formal proof of the existence of the trade-off for most prevailing causal identification strategies. Specifically, I show that the bias caused by exaggeration can be larger than the one caused by confounders. I also study the drivers of exaggeration and show that it increases as the strength of the instrument decreases, the number of exogenous shocks decreases or when controlling for an omitted variable absorbs more of the variation in the treatment than in the outcome.

Finally, I discuss concrete avenues to address this causal exaggeration when carrying out a non-experimental study. First, I advocate for the use of tools to evaluate the potential magnitude and risk of both confounding and exaggeration issues separately. Sensitivity analyses help with the former while power calculations help with the latter. For instance, the sensitivity analysis tools developed in Cinelli and Hazlett (2020) enable to assess how strong confounders would have to be to change the estimate of the treatment effect beyond a given level we are interested in. Prospective power simulations help identify the design parameters affecting power and exaggeration by approximating the data generating process (Gelman 2020, Black et al. 2021). Retrospective power calculations allow to evaluate whether a study would have enough power to confidently estimate a range of smaller but credible effect sizes (Gelman and Carlin 2014, Stommes et al. 2021). Focusing more specifically on the trade-off and its drivers, I present tools to visualize the variation actually used for identification when using causal identification strategies. The companion website describes in details how such analyses can be implemented. Finally, I briefly discuss potential solutions to mitigate this trade-off.

This paper contributes to three strands of the literature. First, the idea that causal identification estimators, while unbiased, may be imprecise is not new; this is part of the well-known bias / variance trade-off (Imbens and Kalyanaraman 2012, Deaton and Cartwright 2018, Hernán and Robins 2020, Ravallion 2020). I approach this literature from a different angle: through the prism

of statistical power and publication bias. Not only the limited precision resulting from the use of causal identification methods could make it difficult to draw clear conclusions regarding the exact magnitude of the effect but I argue that it might also inherently lead to inflated published effect sizes, creating another "bias".

Second, recent studies discussing the exaggeration of statistically significant estimates due to low power focused on specific causal identification methods separately and usually do not investigate the determinants of this exaggeration (Schell et al. 2018, Black et al. 2021, Stommes et al. 2021, Young 2021). In a companion paper, I consider a wide range of causal and non-causal identification strategies and highlight tangible design parameters that can cause exaggeration (Bagilet 2023). In the present paper, I propose an overarching mechanism, inherent to causal identification strategies as a whole, and that can explain these issues: although each strategy does so through different means, in essence they discard part of the variation, thereby increasing the risks of exaggeration. This connection could be exacerbated by the fact that, as noted by Brodeur et al. (2020), publication bias is more prevalent for some methods such as the IV.

Third, this study contributes to the literature on reproducibility in economics (Camerer et al. 2016, Ioannidis et al. 2017, Christensen and Miguel 2018, Kasy 2021). The trade-off presented in this paper may be an additional explanation for observing replication failures in empirical economics, despite the widespread use of convincing causal identification methods.

II Simulations

III Mathematical derivation

In this section, I provide a formal mathematical derivation to prove the existence and to describe the drivers of the confounding / exaggeration trade-off. To do so, I first recall a definition of the exaggeration ratio and discuss its drivers. Then, I derive it for a series of estimators, in the presence of an omitted variable bias, when controlling for the omitted variable, when instrumenting it or running a reduced form analysis. Finally, I show that, for any given omitted variable bias, bias can be greater when controlling for confounders using a causal inference methods than not. A more detailed and extensive proof is available on the companion website.

III. 1 Setting and data generating process

Consider an usual linear homoskedastic regression model with an omitted variable. For all individual $i \in \{1, ..., n\}$, assume that:

$$y_i = \beta_0 + \beta_1 x_i + \delta w_i + u_i \tag{1}$$

where $y_i \in \mathbb{R}$ is the observed outcome of interest, $x_i \in \mathbb{R}$ the observed explanatory variable of interest, $w_i \in \mathbb{R}$ an unobserved omitted variable, $u_i \in \mathbb{R}$ an unobserved error term. $(\beta_0, \beta_1, \delta) \in \mathbb{R}^3$ are unknown parameters. β_1 is the parameter of interest. For readability, we introduce the usual vector notation such that for instance $y = (y_1, ..., y_n)'$ and set $\boldsymbol{\beta} = (\beta_0, \beta_1)'$ and $\mathrm{x}_i = (1, x_i)'$.

We assume homogeneous treatment effects and homoskedasticity, along with the usual OLS assumptions (*i.i.d.* observations, finite second moments, positive-definiteness of $\mathbb{E}[\mathrm{x}_i \mathrm{x}_i']$ and u_i conditional mean-zero and uncorrelated with x_i and w_i). We assume that w_i is unobserved, correlated with x_i and that $\delta \neq 0$. To simplify the derivations, we further assume that the unobserved variable is centred, *ie* $\mathbb{E}[w_i] = 0$. We also assume that the variance of the component of w_i that is orthogonal to x_i (denoted $w_i^{\perp}$) does not vary with x_i. Thus, $\mathrm{Var}(w_i^{\perp}|x_i) = \mathrm{Var}(w_i^{\perp})$. We assume the following data generating process for x_i:

$$x_i = \mu_x + \gamma w_i + \epsilon_i \tag{2}$$

III. 2 Exaggeration ratio and its properties

Following Gelman and Carlin (2014), I define the exaggeration ratio E as the ratio of the expected value of the absolute value of the estimate conditional on the estimate being statistically significant over the true effect.

Definition 1. *For an estimator $\hat{\beta}$ of a true effect of magnitude β_1, with standard deviation σ and for a significance threshold of z_α,*

$$E(\beta, \sigma, \beta_1, z_\alpha) = \frac{\mathbb{E}\left[|\hat{\beta}| \middle| \beta_1, \sigma, |\hat{\beta}| > z_\alpha \sigma\right]}{\beta_1} \tag{3}$$

For a normally distributed estimator

IV Practical Recommendations

We have seen that using causal methods induces a trade-off between avoiding confoundings and exaggerating true effects if the study is under-powered. How can we, as applied researchers using observational data, arbitrate it? Since key pieces of information such as the true effect and the effect of omitted variables are inherently unknown, we cannot directly compute the biases caused by confounders and exaggeration. In this section, I examine how we can however get a sense of threats from both sides of the trade-off and visualize its main driver, the variation used for identification. I then discuss how changing attitudes towards statistical significance and replicating studies could limit the exaggeration issue.

IV. 1 Gauging omitted variable bias

On one side of the trade-off lies the bias caused by confounders. Although it is in essence impossible to measure, tools such as sensitivity analyses are available to gauge its magnitude (Rosenbaum 2002, Middleton et al. 2016, Oster 2019, Cinelli and Hazlett 2020). For instance, the method developed in Cinelli and Hazlett (2020) enables to assess how strong confounders would have to be to change the estimate of the treatment effect beyond a given level we are interested in. It offers bounds for the strength of the association between the treatment and potential omitted variables by weighting it against the measured association between the treatment and observed covariates. A typical conclusion from such an analysis would be: "omitted variables would have to explain as much residual variance of the outcome and the treatment as the observed covariate x to bring down the estimate to a value of β_l". In addition, the authors implement graphical tools to facilitate this comparison. I suggest to use such quantitative bias analyses to evaluate the restrictiveness of the causal approach required to limit the threat of unobserved confounding to acceptable levels.

IV. 2 Evaluating risks of exaggeration

On the other side of the trade-off lies the exaggeration emerging when statistical power is low. As OVB, exaggeration and statistical power are in essence impossible to measure as their computation depends on the true effect which is always unknown. Yet, power calculations can help assess them by making hypothesizes on the magnitude of the true effect. In randomized controlled trials, such computations are not only an established practice but a requirement (Duflo et al. 2007, McConnell and Vera-Hernandez 2015, Athey and Imbens 2016). They are, however, rarely reported in non-experimental studies. This can be understandable if power calculations are perceived only as a way to measure a design's ability to detect an effect when there is actually one.

Yet, taking publication bias and the threat of exaggeration into account highlights the necessity of running power calculations in non-experimental studies as well. A low power or a relatively large variance not only makes it more difficult to detect an effect or to draw clear conclusions about its magnitude when detected but it can also create a bias. Considering the attention given to bias avoidance in the economics literature, I advocate to make power central to non-experimental analyses to limit bias caused by exaggeration. Currently, in causal inference textbooks, very few pages are devoted to statistical power in non-experimental studies (Angrist and Pischke 2009; 2014, Imbens and Rubin 2015, Cunningham 2021). To the best of my knowledge, only two textbooks discuss the matter in depth (Shadish et al. 2002, Huntington-Klein 2021). Results from power and exaggeration calculations would not only be highly informative but could also be reported very concisely in the robustness section of articles.

IV. 2.1 Prospective power calculations

To evaluate the statistical power of a study, the risk of exaggeration and identifying the factors driving it, one can first simulate the design of the study (Hill 2011, Gelman 2020, Black et al. 2021). Simulating a data generating process from scratch requires thinking about the distribution of the variables, about their relationships and can also help underline the variation used for identification. I implemented such fake-data simulations in Section II and provide `R` code to be used as examples in the replication material. In situations where the relationships among covariates are too complex to emulate, one can also start from an existing dataset and add a known treatment effect. I implemented real data simulations in a companion paper and describe their implementation in its replication material (Bagilet 2023).

IV. 2.2 Retrospective power calculations

Running post-analysis power calculations can also help getting a sense of the statistical power associated with a research design. Such *retrospective* calculations allow to evaluate whether the design of the study would produce accurate and uninflated statistically significant estimates if the true effect was in fact smaller than the observed estimate (Gelman and Carlin 2014, Ioannidis et al. 2017, Stommes et al. 2021).

I illustrate how a retrospective analysis works by taking the example of Card (1993) on the relationship between human capital and income. He finds that an additional year of education, instrumented by the distance of growing near a four-year college, causes a 13.2% average increase in wage. The associated standard error is 5.5%. Is there a risk of exaggeration with this design? Since, as noted by the author himself, the estimate is very imprecise we could expect so. Imagine that prior evidence suggests that the true effect is likely close to a 10% increase in wage. We

can then compute the statistical power of the study by drawing many estimates from a normal distribution centered around the hypothesized true effect of 10% and with a standard deviation equal to the 5.5% standard error obtained in Card (1993). Concretely, this proceeds as if we were able to replicate the study many times under the assumption that the true effect was equal to the hypothesized one [1]. Statistically significant estimates (at the 5% level) would on average be roughly equal to 15%, therefore overestimating the true effect by a factor of 1.5. Statistical power, the proportion of estimates that are significant, would be only 44%. Conditional on a 10% true effect size being a reasonable assumption, this study would be under-powered and the risk of exaggeration large.

The usefulness of any retrospective power analysis lies on the assumption regarding the true effect size. Informed guesses about the range of plausible effect sizes can be based on results from meta-analyses or previous studies with a convincing design (*e.g.*, a large randomized controlled trial) [2]. When such information is not available, power calculations can be ran for a range of smaller but credible effect sizes.

IV. 3 Driver of the trade-off

We have seen that the variation used for identification was the main driver of the confounding / exaggeration trade-off. This variation determines the variance of the estimator and thus the amount of exaggeration. In this section, I first discuss the impact of estimator variance and how exaggeration leads to reinterpret the well-known bias/variance trade-off. I then propose to use a tool that enables to visualize where the variation used for identification comes from.

IV. 3.1 Navigating the bias/variance trade-off

In non-experimental studies, estimator variance is often important to the extent that a large variance may lead to a failure to reject the null of zero effect when it is actually incorrect. It makes variance paramount as long as a statistically significant estimate is not obtained. Yet, exaggeration underlines that variance matters, even after that a significant estimate has been obtained.

Obtaining a statistically significant estimate from an imprecise estimator should not necessarily be interpreted as a sign of "success" in getting significance despite the estimator being imprecise. It could however be a warning that this estimate comes from the tails of the distribution and thus inaccurately represents the true effect. Conditional on having obtained a statistically significant

1. Timm et al. (2019), Linden (2019) offer `R` and `Stata` packages that enable to easily run these calculations through a short command: `retrodesign(10, 5.5)`.

2. Note that when such meta-analyses are available, one can use a Bayesian procedure to shrink statistically significant estimates based on the corpus of estimates from prior studies Zwet and Gelman (2021), Zwet and Cator (2021), Zwet et al. (2021) .

estimate, a limited precision can hide a bias: exaggeration. This invites to revisit the well-known bias/variance trade-off: a larger variance can actually lead to a larger (conditional) bias. The bias/variance trade-off can in fact be a bias/bias trade-off. This paper thus invites to pay more attention to the implications of our design choices on the variance of our estimators, even after we obtained statistically significant estimates.

IV. 3.2 Visualizing the driver of the trade-off

Causal inference strategies only leverage a subset of the variation to avoid confounders. However, when this subset is too small, exaggeration arises. Visualizing this variation (and the observations) actually used for identification can help navigate the confounding / exaggeration trade-off. The visualization tool I outline here both leverages the interpretation of causal inference methods as control approaches and builds on a procedure developed in Aronow and Samii (2016) for a different purpose: evaluating external validity of standard regressions.

Aronow and Samii (2016) essentially interprets the estimate of the coefficient of the treatment of interest in a simple linear non-causal regression as a weighted average of individual treatment effects. The weight w_i of individual i is simply the squared difference between its treatment status T_i and the value of this treatment status as predicted by the other covariates X: $w_i = (T_i - \mathbb{E}[T_i|X_i])^2$. If treatment effects are heterogenous, the weighting may lead some observations to be disproportionally (non-)represented in the average effect of the treatment. In that case, the average of treatment is only representative of a subset of the individual treatments, leading to external validity issues.

The parallel with our setting directly follows from this interpretation regardless of whether the treatment is heterogenous or not: observations whose treatment status is well explained by covariates do not actually contribute to the estimation of the effect of the treatment. This may lead to a small *effective* sample size and to exaggeration. In the control approach to causal inference strategies, the more variation in the treatment is absorbed when "controlling" for confoundings, the smaller the effective sample, potentially leading to exaggeration. Aronow and Samii (2016) focused on the representativity of the effective sample for fear of external validity issues. I am interested on in its size for fear of exaggeration.

It might then seem compelling to define this effective sample by proposing a weight value under which the associated observation does not actually contribute to identification. Yet, considering the specificity of each analysis and that exaggeration depends on several factors, including the true effect size, I avoid proposing an *ad hoc* cut-off. Instead, I suggest to visualize the individual weights. It allows to get a sense of where the variation comes from and which are the observations that actually contribute to the estimation. Since applied economics analyses often rely on panel

data, I propose to use a heatmap as a base for visualization, with time on the x-axis and individuals on the y-axis. Figure displays this visualization for the paper

Most of the variation is absorbed by fixed effects, leading only a small subset of observation to actually contribute to the estimation (the darker ones).

If the data is cross sectional, the same heatmap can be computed with individuals on the x-axis and a length-one segment on the y-axis. I display such graphs and share `R` code to build on the companion website.

IV. 4 Attitude Towards Statistical Significance and Replication

Exaggeration only arises in the presence of publication bias. As shown in the simulations, if estimates were not filtered by their statistical significance, even under-powered studies would on average recover the true effect, as long as the estimator is unbiased. The exaggeration issue could there be addressed by tackling publication bias.

To identify broader pathways to eliminate this filtering of significant results, it is first helpful to discuss the processes that lead to statistically significant results when power and thus the probability of obtaining a significant estimate is low. In such situations, they can be obtained either by "chance" or as an outcome of the garden of forking paths (Simmons et al. 2011, Gelman and Loken 2013, Kasy 2021). Forks appear at various stages along the path of research, for instance in data preparation, regarding the inclusion of a given control variable or whether to carry on a research that yields non-significant results. Due to the structural flaw that favors significance, the path followed may be more likely to lead to a statistically significant result. These choices are most often not the result of bad researcher practices but instead a product of a structure that portrays significant results as the end goal of research.

The issue being structural, system level changes in scientific practices could also alleviate exaggeration and the trade-off described in this paper. First, many researchers advocate abandoning statistical significance as a measure of a study's quality (McShane et al. 2019). To be effective, this change should be paired with an effort to replicate studies (Christensen and Miguel 2018). Replications, even of low powered studies, would eventually enable to build the actual distribution of the causal estimand of interest. Meta-analyzes would then reduce the uncertainty around the true value of the causal estimand by pooling estimates (Hernán 2021). Finally, the inflation of statistically significant estimates could be limited by considering confidence intervals as compatibility intervals (Shadish et al. 2002, Amrhein et al. 2019, Romer 2020). The width of these intervals gives a range of effect sizes compatible with the data. Confidence intervals will be wide in under-powered studies signaling that point estimates should not be taken at face value, even if

statistically significant.

V Conclusion

The economic literature suffers from an extensive lack of power (Ioannidis et al. 2017) and many studies showed the existence of a publication bias in this literature (Rosenthal 1979, Andrews and Kasy 2019, Abadie 2020, Brodeur et al. 2020, for instance). We also know that in the presence of publication bias, estimates published from underpowered studies exaggerate true effect sizes, even when the estimators are "unbiased" in the usual sense of $\mathbb{E}[\hat{\beta}] = \beta$ (Ioannidis 2008, Gelman and Carlin 2014, Lu et al. 2019, Zwet and Cator 2021). It is therefore not surprising that many estimates published in economics have been shown to be considerably exaggerated (Camerer et al. 2016, Ioannidis et al. 2017), despite the extensive use of convincing causal inference methods. Yet, determinants for these exaggeration and power issues remain understudied. Focusing on causal methods, I argue that exaggeration may be exacerbated by the foundational component of causal inference: the fact that it only leverages subsets of the variation. Although causal inference strategies enable to avoid confounding, they can also reduce statistical power and thus increase the risk of exaggeration. The same aspect that makes these methods credible can create another type of bias. A systematic reporting of statistical power calculations and analysis of the variation actually used for identification could help avoid falling into this exaggeration trap.
